Developments in Glycaemic Control –
Will New Concepts Result in Improved Management of Diabetes?

Patrick Meyer1 and Jacques Philippe2

The prevalence of diabetes in Europe has been dramatically increasing since the early 1990s. It is estimated that in 2007, 53 million people had diabetes in Europe. Quantitatively, Russia and Germany have the highest number of people with diabetes, with a combined figure of about 17 million. When the age group of 22–79 years is considered, in some European countries – such as Ukraine, Germany and Russia – as much as 10% of the population is affected by diabetes.1 The obvious consequence of the epidemic of type 2 diabetes is an increase in both macro- and micro-angiopathic complications. In 2000, the number of excess deaths due to diabetes was estimated to be 2.9 million worldwide (5.2% of all deaths). The excess death rate in particular concerns the age group from 30 to 75 years.2

Why Do We Need Good Metabolic Control?
There are a number of reasons to achieve good metabolic control. Intervention studies such as the Diabetes Control and Complications Trial (DCCT),3 the UK Prospective Diabetes Study (UKPDS)4 and Steno II5 (carried out by the Steno Diabetes Centre, Norway) have shown the importance of metabolic control in the prevention of diabetic complications. In addition, the large number of people with diabetes incurs enormous health costs if prevention and control are not better achieved. However, long-term control is particularly difficult to achieve because diabetes is a disease in which compliance with treatment and lifestyle is imperative to achieve success. Furthermore, the disease evolves with a progressive loss of β-cell function. Also, the available medications have limitations in terms of efficacy and side effects.

Treatment of Type 2 Diabetes – The New Guidelines
The standard approach to the management of type 2 diabetes is well accepted and simple in theory. At the time of diagnosis, diet, exercise and monotherapy with metformin are widely accepted. When this therapy becomes insufficient, combination therapy with two or three oral agents is started. When necessary, insulin is later added to other therapies, and finally multiple injections of insulin have to be started for a significant percentage of diabetic patients later in the evolution of the disease. The American Diabetes Association (ADA) and the European Association for the Study of Diabetes (EASD) established recommendations for the treatment of type 2 diabetes in 2006.6 Once the diagnosis of diabetes is established, these recommendations propose starting active lifestyle interventions plus metformin.

When these initial measures fail to maintain a glycated haemoglobin (HbA1c) level under 7%, the recommendations are to add insulin, which is the most effective (at least acutely), a sulfonylurea (the least expensive) or a glitazone, which has the advantage of not causing hypoglycaemia. When the second step is unable to maintain the HbA1c level at less than 7%, additional combination therapy is required until intensive insulin treatment is started. Of note, metformin is maintained throughout these different steps. The different antidiabetic medications have similar efficacy, at least during the first year of treatment, and lead to decreases in HbA1c of 1–2%. However, each has advantages and disadvantages (see Figure 1).

Lifestyle changes are low-cost and have many health benefits. Unfortunately, they are usually effective only in the short term because compliance is difficult to maintain. Metformin is weight-neutral and inexpensive; however, it has gastrointestinal side effects with rare episodes of lactic acidosis. Sulfonylureas are inexpensive too, but they cause weight gain and hypoglycaemia. Glitazones markedly improve insulin resistance and triglycerides, but they are associated with fluid retention, weight gain, macular oedema and osteoporosis, and they are also expensive. Finally, insulin has no dose limits, is inexpensive and leads to an improved lipid profile; however, it requires injections and can cause hypoglycaemia and weight gain. Additional treatments such as glinides – which increase insulin secretion similar to sulfonylureas, but with a shorter duration of action – and alpha glucosidase inhibitors – which delay intestinal carbohydrate absorption – may be helpful in the treatment of diabetes, but usually have slightly decreased efficacy compared with the alternative treatments.

New treatments available on the market include glucagon-like peptide-1 (GLP-1) analogues and dipeptidyl peptidase-4 (DPP-4) inhibitors, which improve glucose-dependent insulin secretion and lead to weight loss for the GLP-1 analogues.7 These treatments are based on the observation made several decades ago that enteral nutrition provides a more potent insulinotropic stimulus compared with a comparable glucose intravenous load, leading to the incretin concept. The two incretins identified in the last decade are GLP-1 and glucose-dependent insulinotropic peptide (GIP).8 The first GLP-1 analogue to enter the market is exenatide. Exenatide is a subcutaneously injected incretin mimetic. It is indicated as adjunctive therapy to improve glycaemic control in patients who are already receiving therapy with metformin, a sulfonylurea or both, and who have suboptimal glycaemic control. Exenatide improves glucose homeostasis by mimicking
Exenatide is a promising new treatment for type 2 diabetes, particularly when slow-release exenatide becomes available, allowing ease of use, weight loss and improved glycaemic control.

Liraglutide is the second GLP-1 agonist in development, and one of its characteristics is as a free fatty acid addition to lysine 26. The acyl moiety promotes non-covalent binding to albumin, with 1–2% of liraglutide circulating possessing a non-albumin-bound free peptide. Liraglutide has a longer half-life compared with exenatide and can be given as a once-daily injection. So far, the efficacy and side effects of liraglutide are similar to those of exenatide.

GPL-1 is normally rapidly degraded by DPP-4, a ubiquitous membrane-spanning cell-surface amino peptidase widely expressed in many tissues. The extracellular domain of DPP-4 can be cleaved from its membrane-anchored form and circulate in plasma, where it retains its full enzymatic activity. Many gastrointestinal hormones, neuropeptides, cytokines and chemokines are substrates for DPP-4, among them both GIP and GLP-1, which are the hormones of the two incretins. On this basis, substances that inhibit DPP-4 have been designed. They specifically and potentiy inhibit the enzyme DPP-4 after oral administration. DPP-4 inhibitors have many of the actions observed with GLP-1 analogues, including stimulation of insulin and inhibition of glucagon secretion, preservation of β-cell mass through stimulation of cell proliferation and inhibition of apoptosis, although these latter effects have not been demonstrated in humans. In contrast, DPP-4 inhibitors are not associated with delayed gastric emptying or weight loss.

DPP-4 inhibition is accompanied by a rise in post-prandial levels of intact GLP-1 and GIP. Most studies published so far have been performed with either vildagliptin or sitagliptine. These substances are well tolerated and used as monotherapy or in combination with metformin or glitazones. Their efficacy on glycaemic control is similar to that of metformin, sulfonylureas or glitazones, and they are weight-neutral. No major adverse events have been associated with the use of DPP-4 inhibitors, despite the large number of potential substrates for DPP-4. However, the long-term safety profile of DPP-4 inhibitors is still unclear. For instance, the use of 100mg as a single dose of vildagliptin has resulted in increased liver function tests in a small percentage of patients; furthermore, a slight increase in upper respiratory tract infections has been observed in one study. Overall, agents that enhance incretin actions show great promise for the treatment of type 2 diabetes, with favourable effects not only on glycaemic control but also on weight and, potentially, on β-cell function in the context of a currently favourable safety profile. However, long-term clinical studies are needed to better assess the role and true benefits of these drugs.

Endocannabinoid receptor antagonists such as rimonabant are also helpful in the treatment of type 2 diabetes due to their favourable effects on weight through inhibition of food intake and increased lipolysis. The endocannabinoid system, which is functional in multiple organs including the brain, the adipose tissue, the liver and the pancreatic β cells, is overactive in obesity, probably secondary to a high-fat diet and increased food intake. This creates a vicious cycle, with increased lipogenesis in adipocytes and the liver leading to abdominal obesity and liver steatosis and, potentially, to excessive insulin secretion. Thus, constant activation of the endocannabinoid system may play an important role in the pathophysiology of the metabolic syndrome. Cannabinoid receptor type 1 (CB1) antagonists have multiple actions by blocking the effects of endogenous endocannabinoid on different organs, including...
anorexigenic effects through the hypothalamus, a decrease in motivation for palatable food through the nucleus accumbens, stimulation of anorectic signals through the gastrointestinal tract and glucose uptake by the muscles and inhibition of lipogenesis in the liver and adipose tissue. The hypothetical benefits of CB1-receptor antagonists have generated an ambitious clinical programme to study their effects in patients. Among the multiple studies, some were performed specifically in diabetic patients, including Rimonabant In Obesity (RIO)-diabetes and the Study Evaluating Rimonabant Efficacy in Drug-Naive Diabetic Patients (SERENADE).10,12 In both studies, a decrease of 5–6kg accompanied by a decrease of 5–6cm in waist circumference as well as 0.6–0.7% in the HbA1c level was observed after six to 12 months. Unfortunately, these favourable effects on glycaemic control and weight were accompanied by some serious adverse events, such as depressed mood, anxiety, irritability, insomnia and suicidal thoughts. Thus, depression appears as a formal contraindication to such treatment, and since depression is a common problem in obese patients the use of CB1-receptor antagonists may be limited at present. The full long-term safety profile of these agents needs to be better assessed.

Overall, these new treatments have similar efficacy with respect to the HbA1c level compared with the older ones, their main advantage being the low frequency of hypoglycaemia and their effects on weight. Their respective place in the algorithm for the treatment of type 2 diabetic patients will have to be further defined. It is clear that diabetes is one of the most difficult diseases to treat in the long term. Indeed, the UKPDS1 and A Diabetes Outcome Progression Trial (ADOPT)13 have shown that the HbA1c level – which is invariably improved by any standard treatment at the beginning of the disease – often increases after two years of therapy, indicating that combination therapy is mandatory with time in most diabetic patients. Indeed, after follow-up of nine years in the UKPDS, only 11% of patients were still on diet, 21% on sulfonylureas and 13% on metformin.

Unfortunately, while it is thought that control of diabetes should improve with the availability of more treatments, this is in fact not the case. The US epidemiological National Health and Nutrition Examination Survey (NHANES) revealed that between 1988 and 1994, 44.3% of diabetic patients had an HbA1c level of less than 7%, while a more recent study performed between 1999 and 2000 revealed that this number had actually decreased to 37%, illustrating that despite more evidence in favour of good metabolic control to prevent complications and the availability of more treatment modalities, diabetes treatment remains a difficult task.14 For instance, in the Steno II study the percentage of patients reaching an HbA1c level of less than 6.5% was around 3% with conventional therapy and only 15% with intensive therapy.15 Similar results were observed in Switzerland in five university centres. Indeed, an observational study reported that only 13% of patients treated in the diabetes clinics in these university hospitals had HbA1c levels of less than 6.5%.16

### Why Do We Have So Much Difficulty Controlling Diabetes?

The progressive loss of β-cell function that is already ongoing at diagnosis of diabetes,17 followed by the subsequent lifestyle changes even when patients are intensively educated (see Figure 2), are not always totally effective, as suggested by the Steno II study.18 Also, many of the treatment options in diabetes lead to increases in weight, which may have detrimental effects in the long term. Doctors should also react much earlier in trying to improve diabetes control in their patients. An elegant study showed that at insulin initiation, the average diabetic patient has spent about five years with an HbA1c level of more than 8% and about 10 years with a level of more than 7%.19 Multiple difficulties exist in adapting treatment, particularly starting insulin (see Table 1). Physicians always hope that lifestyle will eventually improve diabetes control; however, patients are often reluctant to take more medications. For insulin, the need for education and the time spent demonstrating the use of specific materials and how to perform injections are major limiting factors. The requirements for more rigorous diet obligations and more frequent blood glucose monitoring, the appearance of more severe and more frequent hypoglycaemia, the problem of weight gain, the risk of more errors and a bad social representation of disease severity are all barriers to starting insulin. This requires good communication skills and time to convince patients that it will be beneficial for them. Although increases in medication or in prescribing insulin may be translated as an increase in disease severity, increased organisation and more risks, this will eventually pay off with a decreased complication rate and an increased lifespan for the patient.

In conclusion, the major difficulties in controlling diabetes are mainly due to psychosocial reasons because of the daily requirements for self-management and compliance, the evolution of the disease and the limitations of the available medications. Thus, new concepts may not mean improved management of diabetes. Improved management of diabetes will require more efforts from both the patient and the doctor. These efforts involve mandatory lifestyle adaptations and increased physician vigour to adapt treatment. However, the development of new treatments may offer major advantages in terms of diabetes control because we need medications that lead to weight loss and improved glucose and lipid profiles, with good tolerance, limited side effects and, eventually, improved life quality and expectancy.
